CSI34: Scope

Announcements & Logistics

- Lab 04 Feedback is out! Can you interpret TestResults.txt?
- HW 5 will due tonight @ 10pm
- Lab 4 Part 2 due Wednesday/Thursday 10pm
- Midterm reminders:
 - Review: Monday 3/11 from 7-9pm
 - Exam Thurs 3/14 from 6-7:30pm OR 8-9:30pm
 - Both exam and review are in Bronfman Auditorium

Do You Have Any Questions?

Last Time: Aliasing

- Attempts to change **immutable** objects (e.g., strings) produce **clones**
 - Changes to clones do not affect originals
 - No aliasing!
- We can create **aliases** of **mutable** objects
 - Aliases refer to the same object, so changes to that object through any alias affect value that other aliases observe
- For the list data type, += is sneakily replaced by .append()
 - This mutates the list!

Goal was to demystify surprising behavior: nothing in computer science is magic!

Today's Plan

- **Scope**: variables, functions, objects have limited accessibility/visibility.
 - Understanding how this works helps us make decisions about where to define variables/functions/objects

Goal is to again demystify surprising behavior: nothing in computer science is magic!

```
a = 3
b = 4
def square(x):
    return x * x
c = square(a) + square(b)
c = pow(c, 0.5)
print(c)
```

```
a = 3
b = 4
def square(x):
    return x * x
c = square(a) + square(b)
c = pow(c, 0.5)
print(c)
```

But also not an error!

Big Question: When we reuse variable names, how does Python know what a variable refers to?

Scope Diagram

- In Gladden & Carter "Mark Hopkins" refers to Mark Hopkins '1824, President of Williams College 1836-1872.
- In TCL, "Mark Hopkins" refers to Professor Mark Hopkins, who started working at Williams in 2022.

Let's see it in python!

scope.py

mar_hop = 111119 # Mark Hopkins '1824 student ID number

```
def gladden():
    al = 223456 # Al's student ID number
    ann = 287654 # Ann's student ID number
    print(al, ann, mar_hop)
def carter():
    brady = 277777 # Brady's student ID number
    blake = 200000 # Blake's student ID number
```

```
blake = 288888 # Blake's student ID number
print(brady, blake, mar_hop)
```

```
def tcl():
```

```
mar_hop = 998877 # Mark Hopkins '2022 student ID number
casey = 212233 # Casey's student ID number
cleo = 233444 # Cleo's student ID number
print(casey, cleo, mar_hop)
```

```
if __name__ == '__main__':
    gladden() # prints?
    carter() # prints?
    tcl() # prints?
```

Let's see it in python!

scope.py

mar_hop = 111119 # Mark Hopkins '1824 student ID number

```
def gladden():
    al = 223456 # Al's student ID number
    ann = 287654 # Ann's student ID number
    print(al, ann, mar_hop)
```

```
def carter():
    brady = 277777 # Brady's student ID number
    blake = 288888 # Blake's student ID number
    print(brady, blake, mar_hop)
```

```
def tcl():
```

```
mar_hop = 998877 # Mark Hopkins '2022 student ID number
casey = 212233 # Casey's student ID number
cleo = 233444 # Cleo's student ID number
print(casey, cleo, mar_hop)
```

if	name ==	1	main	_':	
	gladden()	#	223456	287654	111119
	carter()	#	277777	288888	111119
	tcl()	#	212233	233444	998877

Let's see it in python!

scope.py

mar_hop = 111119 # Mark Hopkins '1824 student ID number

Local Before Global

When python encounters a new term, like a variable or function name, it **first** looks **local**ly, before looking higher up.

If python can't ever find the value assigned to the term, you get a **NameError**.

triple(num) A Small Example

Example: triple(num)

A
def triple(num): in function
 multiplier = 3
 return multiplier * num
answer = triple(5)
print(answer)

C

def triple(num):
 return multiplier * num
multiplier = 3
answer = triple(5) below/after
print(answer)
function def

B function Multiplier = 3 def triple(num): return multiplier * num answer = triple(5) print(answer)

D

def triple(num):
 return multiplier * num
answer = triple(5)
multiplier = 3
print(answer)
after function call

What will each of these print?

Example: triple(num)

Function Frame Model

• By default, Python reads code one line at a time, starting from line 0

```
0 multiplier = 3
1 def triple(num):
    return multiplier * num
2 answer = triple(5)
3 print(answer)
```

At first, when variables are assigned, their values are stored in the global frame

Global Frame

multiplier : 3

- Function definitions are treated like a single line of code
- A **def** statement does **not** call the function, it just defines it

```
0 multiplier = 3
1 def triple(num):
    return multiplier * num
2 answer = triple(5)
3 print(answer)
```

```
multiplier : 3
triple : multiplier * num
```

- Function definitions are treated like a single line of code
- A def statement does not call the function, it just defines it
- Effectively, it assigns the name of the function to a blueprint for computing the function

```
multiplier = 3
0
  def triple(num):
      return multiplier * num
  answer = triple(5)
  print(answer)
```

- To execute an assignment statement, python first computes the value of the expression on the **right-hand side**
- In this case, the **right-hand side** calls the **triple** function

```
0 multiplier = 3
1 def triple(num):
    return multiplier * num
2 answer = triple(5)
3 print(answer)
```

 When a function is called, a new frame is created to record the variables used by that function
 Global Frame

• First, the values of the argument variables are recorded in the call frame

- Then, the lines of the function are executed in order
- To look up the value of a variable, first python looks Global Frame in the call frame multiplier _: 3

- If the variable isn't found in the call frame, then python looks in the parent frame
 - (the frame we were in when the function was called)

• Ultimately, a return value is computed for the function call

• The call frame is destroyed when the function returns

...and the return value of the function call is assigned to variable
 answer in the global frame
 Global Frame

```
0 multiplier = 3
1 def triple(num):
    return multiplier * num
2 answer = triple(5)
3 print(answer)
```

...and the return value of the function call is assigned to variable
 answer in the global frame
 Global Frame

```
0 multiplier = 3
1 def triple(num):
    return multiplier * num
2 answer = triple(5)
3 print(answer)
```

- Finally, the value of answer is looked up in the global frame
- And printed to the screen

0

Function Frame Model: Side-by-Side Example

Let's use these principles to trace the execution of these two programs Side-By-Side

Side-by-Side

def triple(num):
 return multiplier * num

```
multiplier = 3
answer = triple(5)
print(answer)
```

Global Frame

С

def triple(num):
 return multiplier * num
answer = triple(5)
multiplier = 3
print(answer)

Global Frame

def triple(num): return multiplier * num answer = triple(5) multiplier = 3 print(answer)

Global Frame

D
def triple num):
 return multiplier * num
answer = triple(5)
multiplier = 3
print(answer)

More Examples

```
multiplier = 3
def mystery(num):
    return multiplier * num
multiplier = 2
answer = mystery(5)
print(answer)
```

10

```
multiplier = 3
def mystery(num):
    return multiplier * num
multiplier = 2
answer = mystery(5)
print(answer)
```

- multiplier is recorded as 3 on the Global Frame
- Then the mystery() blueprint is recorded on the Global Frame
- Then **multiplier** is re-assigned the value 2 on the Global Frame
- mystery(5) evaluates to 10, since multiplier is 2 in the global frame and num is 5 in the call frame

```
list = 2468
list_str = list("whodoweappreciate")
print(list, list_str)
```

is

ot callable

list = 2468list_str = list("whodoweappreciate")TypeError: ist' print(list, list str) object

- list is a python keyword, in the Global Frame
- list = ... reassigns the value of list in the Global Frame
 - It's no longer the keyword, it's now an integer object
- So you can't call list(...) as the built-in list-casting function!
- ...This is why we should never use python keywords as variable names!!!
